APPENDIX No. 14.

ON THE FLEXURE OF PENDULUM SUPPORTS.

By C. S. PEIRCE, Assistant.

HISTORICAL.

The fact that the rate of a pendulum might be largely influenced by the elastic yielding of its support was first pointed out by Dr. Thomas Young in his article on Tides in the Encyclopædia Britannica, where he gave a correct mathematical analysis of the problem. Kater made use of the noddy, or inverted pendulum of Hardy, to assure himself that its support was sufficiently steady.

Hardy's noddy is a pendulum turning with a reed spring and provided with an adjustable bob. It differs from an ordinary pendulum, first, in being upside down, that is, having its center of mass above its point of support; and second, in having a spring so strong as to act a little more strongly than gravity. The force tending to bring the pendulum to the vertical is then the excess of the force of the spring over the moment of gravity. In this way the noddy is easily adjusted so as to have the same period of oscillation as the pendulum used to determine gravity, while its moment of inertia is very small. In a note at the end of this paper I give the mathematical analysis of this state of things, from which it will be seen that Kater might have constructed his noddy in such a manner as to letect any amount of flexure sufficient to have a serious effect upon the period of his pendulum.

THIS PAGE LEFT BLANK INTENTIONALLY

Bessel, at the end of §3 of his great memoir on the length of the seconds' pendulum at Königsberg, states that he also used Hardy's noddy, and that he swung his pendulum again after stiffening the support. He adds that the effect on the period would probably be the same for his long pendulum as for his short one—a very just remark—which made it less necessary for him to attend to the rigidity of the stand.

attend to the rigidity of the stand.

The construction of English pendulum supports, that of Bassevi, for example, shows that in that country this source of error was never overlooked. It is noticed even in brief accounts in English of the process of measuring gravity. Thus, a writer in the Encyclopædia Britannica proposed to make use of two different reversible pendulums of the same form but of different weights, in order to take account of the xure, an idea lately borrowed by M. Cellerier.

When the reversible pendulum came into use the study of the writings of the older observers seems to have been neglected,* and the grave errors due to flexure were never suspected until Albrecht found a value of gravity at Berlin differing by nearly 2 millimeters from that of Bessel. So little was the true cause of this discrepancy at first suspected that it was paradoxically attributed to the neglect of a buoyancy correction.

In 1875, however, General Baeyer gravely suspected that the period of a pendulum swinging upon a Repsold tripod was affected by the oscillation of the latter, and in a circular addressed to the members of the committee on the pendulum of the International Geodetic Congress, he wrote: "The necessity of suspending the pendulum from a stand is a source of error, since a pendulum swinging on a stand sets the latter into oscillation and so influences the rate of the former. The effect could be diminished by the use of a shorter pendulum and smaller stand; but whether it would be rendered entirely insensible is open to question."

^{*}Thus, Bessel's idea of directly measuring the position of the center of mass was supposed by the Swiss savans to belong to M. Cellerier.

It was at this time that I first received the Repsold apparatus from the makers, of whom it had been ordered two years before, on the occasion of my first being charged with the pendulum operations of the Coast Survey. Becoming acquainted with General Baeyer's doubts, I determined to settle the question by measuring the flexibility of the Repsold tripod at the earliest opportunity. This I did at Geneva, where, though I only madé a rough measurement, I found that the flexure was fully sufficient to account for the discrepancy between the determinations of Bessel and of Albrech

On September 25 of the same year I communicated my result to the standing committee of the Geodetical Congress. At the same sitting the reports of the different members of the pendulum committee were read. Dr. Bruhns said: "The question whether the stand is set into oscillation, and whether the rate of the pendulum is influenced thereby is, in my opinion, well worth investigation. But I should suppose that the stand could be made so stiff as to eliminate this source of error for a pendulum used only as a relative instrument." The views of M. Hirsch, who is so much occupied with the going of time keepers, are interesting. He said: "The fear that the tripod of suspension may also enter into oscillation, unless it be a fact established by direct observations, seems to me unfounded. Indeed, it cannot be supposed that there are any true oscillations of a body of such a form resting on three points. Besides, the movement of the pendulum whose mechanical moment (moment mécanique) is slight on account of its small velocity, could only be communicated to the tripod by the friction of the knife on the supporting plane. Now, this friction is insignificant, as the slowness of the decrement of the amplitude shows, this being almost entirely due to the resistance of the air." It may be observed that the rolling friction of the knife edge is, in truth, very slight, but the amount of the sliding friction is sufficient to hold the knife in place on the supporting plane. Dr. von Oppolzer, the designer of the Repsold tripod in its definitive form, said that the construction of the stand rendered any serious flexure a priori improbable; but he did not support this opinion by any calculations.

During the spring of 1876, having already measured the flexibility of the tripod in Paris, I remeasured it in Berlin, where my experiments were witnessed by General Baeyer and a party of gentlemen attached to the Prussian Survey.

In October, 1876, at the meeting of the standing committee of the International Geodetical Union at Brussels, the result of my experiments was announced by General Baeyer. M. Hirsch described certain experimental researches undertaken by him to ascertain whether there was any such flexure in the case of the Swiss tripod. He had, in the first place, employed an extremely sensitive level, which had not entered into oscillation while the pendulum was swinging upon it. It is not clear why M. Hirsch employed a very sensitive level, the natural time of oscillation of which would differ much more from the period of the pendulum than that of a less sensitive level would do. He also used an artificial horizon in the same way. M. Hirsch's conclusion is that "there remains no doubt that the Swiss stand is free from every trace of such oscillations." Dr. von Oppolzer entirely agreed with the views of M. Hirsch.

In the following summer I addressed to M. Plantamour a paper upon the subject, to be submitted to the next meeting of the Geodetical Congress. In this note, which is reprinted at the end of the present report, I first give a mathematical analysis of the problem. I next show experimentally that the motion of the knife-edge support is not a translation, but is a rotation, so that different parts of the head of the tripod, only a few centimeters distant from one another, move through very different distances. Consequently, measures of the flexure made anywhere except at the center of the knife-edge plane require an important correction before they can be used to correct the periods. This is confirmed by experiments with a mirror while the pendulum is in motion. I next give a brief résumé of my statical measures of the flexure. I then give measures of the actual flexure under the oscillation of the pendulum, and show that the statical and dynamical flexibilities are approximately equal. Finally, I swing the same pendulum upon the Repsold support and upon another having seven times the rigidity of that one, and I show that the difference of the periods of oscillation agrees with the theory.

Immediately upon the reception of my manuscript, MM. Hirsch and Plantamour commenced new researches, designed to form an "étude approfondie de ce phénomène." These were embodied in a paper by M. Plantamour, which was read to the Geodetical Congress, and which has since been

expanded into a memoir entitled "Recherches expérimentales sur le mouvement simultané d'un pendule et de ses supports." M. Plantamour finds fault with me, first, for having measured the flexure with a force five or ten times that of the deflecting force of the pendulum; and second. for measuring the elasticity statically instead of dynamically. The reply to the first objection is that the properties of metals are known to a great extent, that elasticity is not "une force capricieuse," and that no fact is better established than that an elastic strain is proportional to the stress up to near the limit of elasticity, which limit was not approached in the author's experiments. As to the second objection, I had shown by experiment that the statical and dynamical flexures are nearly equal; and I am willing to legive it to time to show whether this will not be assumed in future measures of the flexure of future pendulum supports. M. Plantamour caused a fine point fixed into the head of the tripod to press against a little mirror, mounted on an axis: and then observed the reflection of a scale in a telescope. The length of the path of light from the scale to the telescope divided by the distance of the bearing point from the axis of the mirror he calls the grossissement; so that had he used a fixed star in place of his scale, the grossissement would have been virtually infinite. From the given length of the lever it would appear that a movement of 0".03 in the point would turn the mirror 4". The aperture of the mirror is not stated, but it cannot be supposed that the error of observation would be less than this. It does not seem to me that the use of this mode of measurement, which magnifies the motion but little more than my method, is conducive to accuracy, especially in investigating the difference between statical and dynamical flexure. A certain finite force presses together the point and the lever. Dividing this force by the minute area of pressure, we find the pressure upon the metal is very great. approaching the crushing pressure. Now, the behavior of metals under great pressure is greatly influenced by the time. But my objection is not merely theoretical; I have myself made experiments upon this method, and, making them as skillfully as I could, I still found great uncertainty in the results.

The following table exhibits M. Plantamour's results:

M. Plantamour's flexure experiments.

The table used is the same one shown in Fig. 26 of the Coast Survey Report for 1877. The numbers in the last line above should show the effect of the weight of 3 kilogrammes in diminish ing the flexure of this table under a horizontal force of 100 grammes. The weights used in obtaining the first two numbers were about 100 grammes; but the last column is one tenth the deflection produced by 1,000 grammes. It seems quite incredible that 3 kilogrammes, laid on the table, should really have an effect of this magnitude, so closely proportionate, too, to the deflecting force. It is highly desirable that this result should be confirmed by purely optical experiments; and until this

S. Ex. 49-46

is done, we must suspect that these large numbers indicate some error to which the method of observation is liable. It is certain that the comparator did not act as a brace to stiffen the instrument, and equally so that its weight is not sufficient to alter the modules of elasticity of the brass of the support. It would seem, however, that the effect might be due to a film of some semi-elastic substance under the feet of the tripod. When the tripod is on the floor, no such effect is observed; when it rests on the Geneva pier the dynamical flexure is the same as when it is on the floor, but the statical flexure is much larger. On the Berlin pier the excess of the statical flexure over that on the Geneva pier is five times the dynamical excess. On the other hand, the excess of the dynamical flexure on the table over that at Berlin is half as great again as the statical excess.

MEASURES OF FLEXURE.

My own measures form two series, those made previous to, and those made subsequent to the publication of M. Plantamour's memoir.

In the first series, I was simply occupied in measuring the flexure of the Repsold tripod, as well when properly put up as when the nuts of the bolts were not tightened, of the Geneva support as mounted at Hoboken, and of my "stiffest" support. All the precise measures are statical, and, being made with a filar micrometer, are superior in accuracy to the subsequent ones.

In the second series, the flexures are always measured dynamically as well as statically, and the statical flexure is always found to be the greatest. On the excessively flexible Repsold tripod the difference is sufficient to affect the length of the second's pendulum by 10^μ. Nevertheless, as the axis of motion is different for the two kinds of flexure, there are points at which the motion is less for dynamical than for statical flexure. And in point of fact, when the Geneva support rests on the Geneva tripod, the dynamical flexure of the center of the knife-edge is greater than the statical flexure.

Experiments were also made upon the effect of leaving the nuts of the Repsold tripod entirely loose, of tightening them as much as possible by the hand, and of tightening them by a wrench. It is found that there is little difference between leaving them loose and tightening them by hand, but the effect of the wrench is to produce a stiffening equivalent to a shortening of the pendulum by 20 microns.

Experiments were also made upon the effect of placing a weight of 6 pounds, and afterwards of 25 pounds, upon the head of the Repsold support. The first weight produced absolutely no effect; the second moved the axis of motion a little, and thus caused a slight difference of flexure at some points.

Experiments were also made upon the effect of resting the Repsold support upon blottingpaper, upon blocks of oak, and upon blocks of india-rubber. In every case the difference between the statical and dynamical flexure was much increased.

The pendulum has also been soung on all these different supports and the period of oscillation determined with a view of ascertaining whether the statical or dynamical flexure should be used in calculating the corrections to the periods. The result, as might have been predicted from the mathematical theory, shows that a value intermediate between the two is to be taken. But the best way is to make the support so solid that the difference of the two kinds of flexure must be inconsiderable.

EXPERIMENTS TO DETERMINE THE FLEXURE-CORRECTION.

A.—Flexure of the Repsold stand.

To determine the flexure, a known force was applied statically to the stand, and the resulting deflection was measured. The principal experiments were made in the cellar of the Stevens Institute at Hoboken. The floor of the cellar is of brick laid down in cement directly on the solid ledge. The floor having been carefully cleaned, the three brass pieces which support the screwfeet of the Repsold tripod were laid down upon it, and the tripod itself was set up. The binding-screws of the feet were screwed up very tight. The pendulum, comparator, and meter were not placed on the tripod, but a mass of iron about equal to them in weight was placed on blocks on the lower part of the tripod in order to ballast it. To apply the force, a silken cord was wound round

the tongue upon which the pendulum usually rests, just in the slot over which is the middle of the knife-edge, in such a manner that the cord when stretched horizontally was exactly at the level of the knife-edge. The cord passed horizontally and perpendicular to the knife-edge to a pulley-wheel over which it passed, and from which it hung down vertically; and to its extremity was attached a kilogramme. The pulley-wheel was one which belonged to an Atwood's machine; it turned with very little friction and its rim was accurately plane and perpendicular to the axis. This wheel rested on a stout wooden tripod; its axis was carefully adjusted to be parallel to the knife-edge and the upper part of the rim was brought to the level of the knife-edge. The usual position of the knife edge is here referred to; but the pendulum was not actually in position. In the measurements of flexure, one person gently raised and lowered this weight alternately. The measurement of the deflection was made by another person, as follows: A micrometer scale on glass was fixed, either to the tongue or to an arm solidly fixed to the tongue, in such a way that the direction of measurement was parallel to the force applied to the tripod. This micrometer scale was observed by a microscope magnifying about fifty diameters and provided with a filar micrometer. This microscope was mounted on a separate, very stiff, iron stand resting on the floor, and carrying at its head a brass apparatus for holding the microscope. The optical axis of the microscope was made exactly parallel to the knife-edge and the filar micrometer screw was made parallel to the force applied to the stand, and the microscope was focused on the micrometer scale. Each division of the scale usually employed was about 12". The filar micrometer wire (which was vertical) was made to bisect one division of the scale and the micrometer was read; it was then made to bisect another division, by turning the screw through about one revolution, and the micrometer was read again. Thus, the value of the revolution was obtained. The weight was then put on, and pointings were made upon the same two divisions. Then, the whole process was repeated until the weight had been put on five times. This made one set of experiments.

The following experiments were made to determine the position of the axis of rotation of the knife-edge support during flexure.

Hoboken, March 10, 1877. Ther. 13° C.—The micrometer scale, attached to an arm, was placed on the line of the knife-edge $53^{\rm mm}$ in front of the anterior extremity of the tongue. The following were the readings of the filar micrometer on one of the lines of the scale with the weight alternately on and off (ρ throughout signifies a revolution of the micrometer screw):

Weight off.	Weight or
ρ	P
10. 955	11.324
. 968	. 320
. 978	. 324
· .	
Means 10. 967	11.323

Difference, +0°.356.

The arm was now length ned so that the scale was 318mm in front of the end of the to gue. The following readings of the filar micrometer were now made:

277 1 2 / 02	*** * 1
Weight off.	Weight on.
ρ	ρ.
10. 344	10.762
. 350	. 776
.341	. 793
. 335	. 778
. 330	.772
 -	
leans 10. 340	10.776

Difference, +0p.436.

The micrometer-scale was next carried over to the other side of the instrument so as to be 496mm behind the front end of the tongue. The following readings were now made:

		Weight off.		Weight on.
			(2.7	ρ
		10. 106		10.324
		. 120		. 334
		. 141		. 334
		. 124		. 340
		. 136		. 340
	Means	. 10. 125		10, 336
Difference, +	0°.211.	Ţ.,	•	

It will be understood that in all these experiments the arm to which the scale was fixed was attached to the tongue on which the pendulum rests, and that this arm was subjected to no force.

The above results are satisfied by supposing that the axis of rotation cuts the level of the knife-edge 1^m.258 behind the end of the tongue. The following table shows the agreement of the observations with this supposition.

Distance forward of	T21-	
	1.16	xure)
end of tongue.	Obs.	Calc.
10 (10 m) (10 m) (10 m)	ρ	ρ
+0.318	0. 436	0.433
+0.053	0.356	0.361
-0.496	0. 211	0.212

The scale was next (March 12, 1877, observer, Edwin Smith) fixed at 395mm vertically below the end of the tongue. The following measures were then made:

Weight off.	Weight on.
ρ	μ
13. 739	13. 260
. 700	. 247
. 710	. 261
. 700	. 260
. 702	. 243
.710	• • • • • •
Means 13.710	13. 254

Flexure, $+0^{\rho}$.446.

The filar micrometer was here in the reverse position from its usual one, and hence the reading with weight off is greater than with weight on.

The scale was next placed 44° above the point of support and the following measures were

Weight off.	Weight on.
ρ	ρ
10. 523	10. 737
453	. 645
. 400	.578
10. 459	10. 653

Deflection, -0º.196.

The filar micrometer was so shaky in this position that accurate measures could not be obtained, but the above answers the purpose.

The scale was next fixed on the end of the tongue and the three measures given below (series 18, 19, 20) were made. The mean of these gives a flexure of 0.340. These measures show that the axis of rotation cuts a vertical from the end of the tongue at a height of 1.07 meters above the level of the knife edge. Thus we have on this hypothesis:

istance below	Fle	exur	θ.
knife-edge.	Obs.		Calc.
m	ρ	•	ρ
-0.44	0.196		0.196
0.00	0.340		0.332
+0.395	0.:446		0.452

A large series of experiments were made at Hoboken to determine the amount of flexure. Of these, the following are chiefly relied upon:

HOBOKEN, March 7, 1877. Ther., 59°.15 F. 3h 12m P. M.

Möller's glass scale of hundredths of millimeters was fixed 3 millimeters above the end of the tongue. The filar micrometer wires remained fixed, and readings of the micrometer scale were made on the two wires, alternately with weight off and on.

The middle of the knife-edge being 30^{mm} behind the end of the tongue, which is $1^{m}.258$ forward of the point where the axis of rotation crosses the knife-edge produced, it follows that $\frac{30}{125}$ of the flexure observed at the end of the tongue, or $0^{\mu}.8$, has to be subtracted from that quantity to get the flexure of the middle of the edge. The latter is, therefore, $34^{\mu}.1$.

Measures of the flexure were also made on the 8th and 12th of March, by Sub-assistant Edwin Smith. The following are his results:

It will be seen that there is a rather large difference between the results of the two observers. It will, of course, be understood that the discordances of single readings are due mainly to relative movements of the micrometer and the pendulum-support. As most of the sources of constant error tend to make the observed values too small, the larger result has been preferred. When the binding screws of the feet were not perfectly tight the flexure was still greater, as is shown by the following means of sets of observations made under those circumstances:

	Flexure.	Diffence from
21st set, 1877, February 17		-0.4
22d set, 1877, February 17	. 37.9	+1.0
23d set, 1877, February 17		-0.8
24th set, 1877, February 17	. 37.8	+0.9
25th set, 1877, February 17	. 36.9	0.0
26th set, 1877, February 19	. 35.3	-1.6
27th set, 1877, February 19	. 37.6	+0.7
Mean	36.9	±0.3

The flexure of the Repsold stand was also measured in Geneva, Paris, and Berlin. In Berlin the microscope was mounted on a wooden stand, which rested on the same pier as the tripod. This was to avoid including the flexure of the pier, which is best measured separately. The micrometer scale was simply fixed to a piece of wood, which was laid on the brass pieces at the ends of the

tongue. This wooden piece projected 35^{mm} beyond the tongue, and consequently 1.7 has to be subtracted from the observed results to get the flexure at the middle of the knife-edge. The following are the means of sets of ten measures:

	Flexure.	Difference from mean
1 - 1 - 1 - 1 - 1 - 1 - 1 - 1 - 1 - 1 -	μ	μ' '
1876, May 24, a. m	35.8'	+0.1
1876, May 24, p. m	35. 7	0.0
1876, May 24, p. m	35. 8	+0.1
1876, May 24, p. m	35.9	+0.2
1876, May 25, a. m		-0. 2
1876, May 25, a. m		—0. 3
		-
Mean	35. 7	± 0.1

This result agrees well with that obtained at Hoboken. Thus:

	i.	•	-				ure of mid- of knife-	
		. • 3		•		ed	ge under 1 ogramme	
Hol	oken	(C. S.	P., ol)servei)		34.1	$^{\mu}$ 215. 2
Ber							34.0	214.5

The same value was found in a rough measure made at Geneva, September 13, 1875.

Much larger values were obtained in Paris, which agree with those found at Hoboken when the binding-screws were not tight. Thus we have

		Flexure with bind- ing-screws loose.	. • .
Hoboken		36.1	227. 8
		36.3	229. 1
Paris, 1876.	March 7	37.1	234, 1

B .- Flexure of the stiffest support.

This support was constructed in order to test the calculated effect of the flexure of the stand. The following table shows the results of measures of its flexure:

Distance of scale forward of center of knife.	Distance below knife.	of scale level of	dir for	ection + in the ection of the ce, - in the op- alte direction.
mm.	m	m.		щ
+ 30		83		+ 5.2
+ 30 💞	_	33		+ 5.2
+ 80 ·	+1	003		-42.5
+335	- +1	003		-36.7

It follows from this that the axis of rotation cuts the line of the knife-edge 166^{min} behind the center of the edge, and cuts the vertical from that center 68^{min} below the edge. Also, that the deflection of the middle of the edge under a force of 1 kilogramme's weight is 3^m.1. This includes the flexure of the pier.

C .- Flexure of the Geneva support and pier.

In measuring this flexure, instead of a low-power microscope and filar micrometer a high-power microscope and eye-piece micrometer were used. A stage micrometer was always observed, and the value of the divisions of the eye-piece micrometer determined by it. In the following experiments the scale was 254mm above the level of the knife-edge and 25mm forward of the middle.

1878, OCTOBER 1.

Flexure,		$6.6 = 16^{\mu}.1$

1878, OCTOBER 19.

The scale was fixed 111cm below the knife-edge, and three sets of 10 gave for the deflection

1878, OCTOBER 21.

The scale was fixed 244 millimeters above the knife edge, and 356 millimeters forward of the middle. Two sets gave as the deflection

$$+13.5$$
 $+12.2$
 $+12.8$

From these measures we find the flexure at the middle of the kuife-edge to be 44.05.

EXPERIMENTS AT PENNSYLVANIA GRAVITATION STATIONS.

ALLEGHENY.

Statical flexure of Geneva support on iron bars. Weight and pulley employed. Weight= 2^k ; f_0 denotes flexure produced by a horizontal force equal to the weight of pendulum (6^k .308).

1879, FEBRUARY 18.

Scale 3-inch (=2cm) above, and 12.5 inches (=32cm) forward of middle of knife-edge; 22.4 div. of scale=100 μ . C. S. P., observer.

1879, MARCH 4.

Scale 1 inch (=2cm.5) above, and 13½ inches (34cm.5) behind middle of knife-edge; 26.7 div. of scale=100". H. Farquhar, observer.

Scale next put 2cm above and 14 inches (=35cm) forward of middle of knife-edge; 26.7 div. of scale= 100^{μ} .

1879, MARCH 6. .

Scale on level of knife-edge and 15 inches (=38cm) forward; 38.5 div. of scale=100\mu.

Scale next put 55 inches (=140cm) below middle of knife-edge; 33.3 div. of scale=200s.

The following is a summary of the above. Fo here and elsewhere denotes the flexure at the middle of the knife-edge under a horizontal force equal to the weight of the pendulum. A=distance from middle point of knife-edge to its intersection with axis; B=distance from middle point

of knife-edge to the intersection of axis with vertical line.

C. S. P.'s observations.

 $\frac{3}{4}$ inch above, 32^{cm} forward of knife-edge, $f_0=16.1$ $\frac{1}{2}$ inch above, 32^{cm} behind, $f_0=55^{\mu}.7$... Flexure at 26m above=35\(^{\mu}\).9 $A=58^{cm}$.

H. F.'s observations.

 2^{cm} .0 above, 35^{cm} forward of knife-edge, $f_0=12^{\mu}$ $2^{\text{cm}}.5 \text{ above, } 34^{\text{cm}}.5 \text{ behind, } f_0 = 64^{\mu}$.. Flexure at 2cm above=384.18 A=51cm. 140cm directly below middle of knife-edge, fo=156. .. $F_0 = 40^{\mu}.66$; A (mean) = 54^{cm} , $B=29^{cm}$.

EBENSBURG.

At this station the Repsold tripod stood on a hard floor of clay. Statical flexure measured by means of weight of 1.0818k. C. S. P., observer.

1879, SEPTEMBER 26.

The two screw-taps binding the front legs of the tripod to top of the stand were first tightened by hand. Scale on the level of the point of suspension, 50cm to the right, and 18cm. 4 forward of middle of knife-edge. 21.6 div. of scale=.001 inch.

	. 1	بسد		1	1	1

It will be seen that the effect of loosening the front taps is to increase the angular flexure about the instantaneous axis. But this axis is at the same time brought forward, and the consequence is that the flexure at the middle point of the knife-edge is not much changed. That the flexure of the tripod alone, without that of the tongue supporting the pendulum, appears, when measured, $40^{\rm cm}$ behind the middle point, to be greater than the combined flexure of the two, is no doubt due to the axis of flexure of the tongue cutting the level of the knife-edge only a short distance behind the middle point. The effect of loading the base of the tripod with bricks was to make it slightly stiffer when wrench-tightened, and considerably stiffer when hand-tightened. All of these measures of flexure seem, however, to be in error, and it seems likely that the position of the scale, when in front of the stand, was not really $184^{\rm mm}$ as recorded, but perhaps $584^{\rm mm}$. With that change, these measures would agree with others, which they do not now do.

The following are dynamical measurements. The pendulum swung heavy end down; 21.4 div. of scale=.001 inch. Are expressed in ten-thousandths of the radius. Screws wrench-tightened; scale 41cm.4 behind, 0cm.7 above knife edge.

•	15.6	16. 7		
	14. 4	15.6		~

Summary of observations, dynamical and statical, made at York, with pendulum on Geneva support.

#### Screws wrenched.

			Dynam.	Stat.
46cm.0 f	forward of knife edge,	$f_0$ :	$= 40 \mu.0$	39 4.3
$52^{\mathrm{cm}}.5$	ck of knife edge,	$f_0$ :	= 70 4.7	65 4.7
•		. F ₀ :	= 56 4.4	53 ±.4
		A:	=181cm	$199^{\mathrm{cm}}$
	$\mathbf{F_0}$	: A	0.312	0. 268

#### Screws loose.

46cm.0 forward of knife-edge, 52cm.5 back of knife-edge,	$f_0 = 40 ^{\mu}.6$ $f_0 = 69 ^{\mu}.4$	31 #.9 70 #.9
	$F_0 = 59 + 9$	52 r.7
	A=192cm	133cm.
F	. A 0.202	0.306

The statical measures are evidently unreliable. The dynamical measures show that the binding screws have no effect.

# 1879, DECEMBER 21.

Repsold stand; the three legs hand tightened both above and below. Statical observations with weight and pulley; weight used=1^k; 27.78 div. of scale = .001 inch. Scale 56^{cm}.7 in front of knife-edge.

NOTE.—The weight put on stand was a very heavy paper weight. Observer troubled all day by tremor; every passer by on the street, every one entering the building, or even the adjoining building, agitates the apparatus so as to make it impossible to read the scale.

Summary of observations with weight and pulley, on Repsold stand, at York.

	Nuts hand-tightened above and below.		Nuts wrenched above and below.	Binding-screws extra tight.	Binding-screws loose,	·Weight on.

These measures are interesting as showing that while the dynamical flexure at the point of application of the force is constantly less than the statical, yet the angular flexure is less in the statical experiments than in the dynamical ones. This fact probably indicates the cause of the difference between the two kinds of flexure, namely, that in the dynamical experiments the flexure wave has not had time to fully reach the distant parts of the apparatus.

The above experiments of April, 1880, were made with a view of testing experimentally the question of whether the statical or dynamical flexures should be used in reducing the periods of oscillation, or whether some intermediate value would be preferable. The pendulum was actually swung upon all these supports. Unfortunately, the measures of flexure of the excessively flexible supports are extremely discordant.

Repsold support on rubber blocks.

when are	11(3))	17.42.	804	$\alpha 13$			891	811.

From the circumstances of the experiment, the results of the second day are to be absolutely preferred. The pendulum was swung on this support on April 18 and 20. The measurements of the flexure of the Repsold tripod on an oaken support are still more utterly discordant. The second experiment of April 21 seems to be the best, and this gives F₀=354* for the statical flexure, and the dynamical flexure appears to be very little less. For the stiffest support we have  $F_0 = 62^{\mu}9$ . statical; dynamical not measured.

The details of the experiments to determine the periods of oscillation on these supports will be given in another report. The following are the results:

#### Stiffest support.

April 20,	703	, 610
	Mean, 1.006705	1.006611

Let us now try the dynamical correction of these periods. For the Repsold support the dynamical  $F_0=237^{\mu}$ ; thence we deduce the corrections for the other supports, as follows:

Heavy end down.	
	Heavy end up.
1. 006500	s. 1, 006509
-84	-36
1. 006416	1. 006473
1, 006439	1, 006475
1, 006540	1.006529
1, 006705	1.006611
The state of the s	
23	2
124	- 56
289	138
	1. 006500 -84 1. 006416 1. 006439 1. 006705 23 124

The values of F₀, calculated from these corrections, are as follows:

Stiffact current	μ	μ
beinest support,	65	13
Oaken support,	 352	371
India rubber,	 821	915

Of course, extremely little weight is to be attached to the values calculated from "heavy end up." For the stiffest support and the oaken support the result is in very good accord with the statically observed flexure. For the India rubber support the dynamically observed flexure seems to be indicated, or rather something between this and the results of statical measures.

#### General conclusions.

- 1. The flexibility of almost any pendulum support has an important effect on the time of oscillation, and should be measured.
- 2. The flexure rotates the knife-edge about an axis, sometimes not over 60 cm. distant. It is, therefore, altogether erroneous to measure the flexure at any other point than the middle of the knife-edge, unless it be measured at a number of points and reduced to that point.
- 3. On a properly constructed support the difference between the statical and dynamical flexure should be immaterial. The dynamical flexure is less than the statical, owing to the time region of the transmission of the wave of strain to the more distant parts of the apparatus. The dynamical flexures, but pretty decidedly nearer to the latter.
- 4. A support like the Repsold tripod will grow more flexible with time, owing probably to the slight loosening of some parts.
- 5. Any dirt, cement, or other elastic film under the feet of such a tripod may greatly increase the flexure, as well as the difference between the two kinds.
- 6. If the flexure is considerable, it is likely to vary from day to day, or eyen during the course of an experiment.
  - 7. The tightening of the parts may or may not greatly affect the flexure.
  - 8. The loading of the support has no sensible effect.
- 9. Experiments made with weight and pulley give a larger value for the flexure than those made with the pendulum drawn to one side.

The theory of Hardy's noddy is very simple. When two pendulums oscillate on the same support in parallel planes, I have shown (Am. Jour. Sci., third series, xviii, 113) that one of the differential equations is

 $\lambda D_i^2 \varphi + D_i^2 s = -\gamma \varphi,$ 

where

t is the time;

 $\varphi$ , the instantaneous angle of inclination of one pendulum;

- s, the instantaneous linear displacement of its knife edge from the position of repose;
- $\lambda$ , the virtual length of the pendulum;
- y, the vertical acceleration of each particle, or the constant of force of restoration of the pendulum.

The Lordy's noddy is a pendulum placed on the support of another pendulum so as to oscillatin a paral. Plane. Its natural period  $\tau = \phi \int_{\gamma}^{\lambda}$  is as nearly as possible equal to T, the period of the main pendulum; but  $\gamma$ , instead of being gravity, is the excess of the force of a spring over gravity and is made to be as small as possible,  $\lambda$  being correspondingly small, so as to give  $\tau$  the right value. The noddy being very light, the value and changes of s are determined entirely by the main pendulum. We may, therefore, write

$$s = S \cos \frac{t}{w}$$

Substituting this value in the differential equation, the solution of the latter is

$$\varphi = \theta \cos \frac{t - t_0}{\tau} \odot - \frac{1}{\chi} \frac{S \odot^2}{-T^2} \cos \frac{t}{T} \odot.$$

But the noddy has no oscillation to begin with. This fact is represented by the equations

$$t_0=0 \qquad \qquad \phi = \frac{1}{\gamma} \cdot \frac{S \odot^2}{\tau^2 - T^2}$$

S. Ex. 49-54

We thus have

$$\varphi = \frac{1}{y} \cdot \frac{S \odot^2}{\tau^2 - T^2} \left( \cos \frac{t}{\tau} \odot - \cos \frac{t}{T} \odot \right) = \frac{2}{y} \cdot \frac{S^2 \odot^2}{\tau^2 - T^2} \cdot \sin \frac{\tau - T}{2\tau T} t \odot \cdot \sin \frac{\tau + T}{2\tau T} t \odot \cdot \sin \frac{\tau + T}{2\tau T} t \odot \cdot \sin \frac{\tau - T}$$

This equation shows that the noddy oscillates with a period that is a sort of mean between its natural period and that of the large pendulum. The amplitude of oscillation increases from nothing at an initial rate equal to

$$\frac{S \odot^3}{\gamma(\tau+T)\tau T};$$

a rate not much affected by the value of  $(\tau-T)$ . But the amplitude increases more and more slowly, and reaches its maximum when

$$t = \frac{\tau T}{\tau - T}$$

after which it again diminishes and after the lapse of an equal time vanishes. At the beginning, the phase of motion of the support is  $\frac{1}{2}$ , and that of the noddy is 0, so that the support is one quadrant ahead. At the time of the first maximum the phase of the support is

$$\left(\frac{1}{2} + \frac{\tau}{\tau - T}\right)$$

and that of the noddy is

$$t_{\tau-T}^{\tau+T}$$

Subtracting the second from the first we see that the two motions are in opposition. When the motion of the noddy vanishes its phase is a quadrant in advance of that of the support. The motion immediately recommences, but

in 
$$\tau$$
-T_t

is now negative, and this shows that the difference of phase changes to the opposite quadrant, and that the two oscillations again proceed toward opposition.

We have thus far not taken account of the resistance to the motion of the noddy, although this must evidently be large. In consequence of it, the natural motion of the noddy would be of the form

$$\varphi = \Phi_{\mathfrak{O}} - \frac{t}{\theta} \circ \cos \frac{t}{2} \odot$$
.

From this we easily infer that the differential equation is

$$D_c^2 \varphi + 2 \frac{\langle e \rangle}{\theta} D_c \varphi + \frac{\Theta^2}{\tau^2} \varphi = \frac{S \Theta^2}{\lambda T^2} \cos \frac{t}{\Psi} \langle e \rangle$$

The solution of this is

$$\varphi = \frac{S}{\lambda} \frac{1}{\theta^{2}(\tau^{2} - T^{2})} + \frac{\tau^{2} - T^{2}}{\tau^{2}} \left( \bigcirc^{-\frac{t}{\theta} \odot \cos \frac{t}{\tau}} (\cdot) - \cos \frac{t}{T} \odot \right) + \frac{S}{\lambda} \frac{\theta(\tau^{2} - T^{2})}{\theta^{2}(\tau^{2} - T^{2})} + \frac{t}{\tau^{2}} \sin \frac{t}{T} \odot \cdot \frac{\theta(\tau^{2} - T^{2})}{\theta^{2}(\tau^{2} - T^{2})} + \frac{\tau^{2} - T^{2}}{\tau^{2}} \sin \frac{t}{T} \odot \cdot \frac{\theta(\tau^{2} - T^{2})}{\theta^{2}(\tau^{2} - T^{2})} + \frac{(\tau^{2} - T^{2})}{\tau^{2}} + \frac{(\tau^{2} - T^{2}$$

The signification of this is that the noddy approaches indefinitely toward settling down to an oseillation strictly synchronous with that of the support. Its ultimate amplitude is very little less than half what the maximum amplitude would be without resistance. But the phase may differ very much from that of the motion of the support. Namely, if the noddy is in precise adjustment to the period of the large pendulum, its phase will be one quadrant behind that of the support. . If the noddy naturally oscillates slower than the large pendulum, its phase may be anywhere from one quadrant in arrear to opposition; if the noddy naturally oscillates faster than the pendulum, it may be anywhere from one quadrant behind, to coincidence.

If, then,  $\gamma$  is one tenth of gravity,  $\tau^2 - T^2$  one thousandth of a second, and S one tenth of a micron, the amplitude of movement of the noddy will be one thousandth of the radius, a quantity easily measured with a microscope.

ON THE INFLUENCE OF THE FLEXIBILITY OF THE SUPPORT ON THE OSCILLATION OF A PENDULUM.

(Translated from French into English by the author.)

NEW YORK, July 13, 1877.

DEAR SIR: On taking charge of the Coast Survey researches upon gravity, I ordered of Messrs. Repsold a reversible pendulum, to be a copy of that of the Prussian Geodetical Institute. But the instrument makers were at that time so taken up with the construction of instruments for the Transit of Venus, that the pendulum was only ready in the spring of 1875. I then went to Hamburg to receive it; and from Hamburg I went on to Berlin, where I found General Baeyer rather dissatisfied with the results obtained with the Prussian instrument. He specially mentioned the flexibility of the tripod, a source of error which pendulum experimenters have surely never overlooked. The pendulum apparatus that I had carried with me from America having been ruined in transportation, I was under the necessity of employing the new instrument, and therefore undertook to measure and take account of the error in question.

A pendulum support might be rickety, so that the pendulum in its oscillations should throw the knife-edge plane from one position to another, without its undergoing any resistance to the motion other than inertia and friction, between two fixed points. This, however, does not happen in the case of any of the supports that I have examined; for, upon observing their behavior under a high-power microscope, I have always found that they spring back exactly to their original position after every flexure that I have applied to them. In short, the movement with which we have to do is the oscillatory flexure of an elastic body. The amplitude of the oscillation is, at most, about 1/5000 of that of the lower knife-edge of the pendulum, so that its square may be neglected.

The plane of support of the knife is itself undoubtedly bent during the movement; but I neglect this and limit myself to the consideration of the movement of its middle point. When to this middle point is applied a horizontal force perpendicular to the knife edge, the latter describes a movement of revolution around an axis which, in the case of the Repsold apparatus, is situated behind and above the tripod at a distance of about a meter from the knife edge. We can neglect the difference between this movement and a translation, until we come to measure its amount. There is also a minute variation in the vertical pressure of the pendulum on the support, but this is yery far from producing any sensible effect on the period of oscillation.

Let us denote by

m the mass of a particle,

r its distance from the knife edge,

ω the inclination, at rest, to the vertical of the perpendicular let fall from the particle on to the knife-edge,

M the mass of the pendulum,

I the length of the corresponding simple pendulum,

h the distance of the center of mass from the knife-edge,

T the period of the osci" tion,

g the acceleration of gravity.

ε the elasticity of the support,

 $\varphi$  the instantaneous inclination of the pendulum to its position of rest,

s the instantaneous displacement of the middle point of the knife-edge from its position of rest

t the time.

Then, the horizontal velocity of a particle will be

$$r\cos(\varphi+\omega)D_t\varphi+D_ts$$

and its vertical velocity will be

$$r \sin (\varphi + \omega) D_i \varphi$$
.

Its living force will, therefore, be

$$\frac{1}{2}mr^2(\mathbf{D}_t\varphi)^2 + mr\cos(\varphi + \omega)\mathbf{D}_t\varphi, \mathbf{D}_t\mathbf{s} + \frac{1}{2}m(\mathbf{D}_t\mathbf{s})^2,$$

and that of the pendulum will be

$$\frac{1}{2} Mlh (D_t \varphi)^2 + Mh \cos \varphi. D_t \varphi. D_t s + \frac{1}{2} M (D_t s)^2.$$

The living force of the motion of the support itself may be left out of account since it involves the square of an excessively small velocity.*

The differential of the potential energy is

$$Mgh \sin \varphi, d\varphi + \varepsilon s, ds$$
.

There is really a third term to be added to this expression dependent on the molecular friction of the matter of the support. But I think we may neglect this term; for its effect cannot be very great, and its coëfficient is, at any rate, unknown.

From the expressions for the living force and potential we deduce the Lagrangian equations

$$lD_t^2 \varphi + \cos \varphi$$
.  $D_t^2 s = -g \sin \varphi$ 

$$-h\sin\varphi$$
.  $(D_t\varphi)^2 + h\cos\varphi$ .  $D_t^2\varphi + D_t^2s = -\frac{\varepsilon}{W}s$ 

or, neglecting terms of the second degree,

$$iD_t^2 \varphi + D_t^2 s = -g\varphi$$

$$kD_t^2 \varphi + D_t^2 s = -\frac{\varepsilon}{\mathbf{U}}s.$$

[Note.—1882, July 24.—I omit the solution of these equations as originally given, and substitute the following, which is perhaps less inelegant. Subtracting the second equation from the first, we get

$$(l-h)D_{i}^{2}\varphi+g\varphi=\frac{\varepsilon}{M}s$$

O1

$$D_t^2 s = \frac{M}{\epsilon} (l - h) D_t^4 \varphi + \frac{Mg}{\epsilon} D_t^2 \varphi$$

Substituting this value in the first differential equation, we have

$$\frac{M}{\varepsilon}(l-h)D_{t}^{4}\varphi + \left(l + \frac{Mg}{\varepsilon}\right)D_{t}^{2}\varphi + g\varphi \triangleq 0.$$

Separating the operator into factors, and using the abbreviation

$$i = 4 \frac{Mg}{\varepsilon l} \cdot \frac{1 - \frac{h}{l}}{\left(1 + \frac{Mg}{\varepsilon l}\right)^{\frac{1}{2}}}$$

we get

$$\left[D_{i}^{2} + \frac{\varepsilon l + Mg}{2M(l-h)}(1+\sqrt{1-i})\right] \cdot \left[D_{i}^{2} + \frac{\varepsilon l + Mg}{2M(l-h)}(1-\sqrt{1-i})\right] \varphi = 0.$$

The solution of this is

$$\varphi = \mathbf{A}_1 \cos \left( \sqrt{\frac{\varepsilon l + \mathbf{M}g}{2\mathbf{M}(l-h)}} (1 - \sqrt{1-i}) \cdot t + \eta_1 \right) + \mathbf{A}_2 \cos \left( \sqrt{\frac{\varepsilon l + \mathbf{M}g}{2\mathbf{M}(l-h)}} (1 + \sqrt{1-i}) \cdot t + \eta_2 \right)$$

where  $A_1, A_2, \eta_1, \eta_2$  are arbitrary constants. On neglecting the square of  $\frac{Mg}{\epsilon l}$ , this reduces to

$$\varphi = \Lambda_1 \cos \left( \sqrt{\frac{g}{l}} \left( 1 - \frac{Mg}{\epsilon l} \right) \cdot t + \eta_1 \right) + \Lambda_2 \cos \left( \sqrt{\frac{\varepsilon}{M} \cdot \frac{1 + \frac{Mgh}{\epsilon l^2}}{1 - \frac{h}{l}}} \cdot t + \eta_2 \right)$$

The second term represents a mere tremor, for its period is very short, owing to the large value of  $\epsilon$ . The period of the first harmonic constituent is

$$T = \sqrt{\frac{l}{g}} + \frac{M}{\varepsilon}$$

From the value of  $\varphi$  and the first equation of this note, we deduce the following value of s:

$$s = \frac{Mg}{2\varepsilon} \left( -\frac{\varepsilon l}{Mg} (1 - \sqrt{1 - i}) + 1 + \sqrt{1 - i} \right) \Lambda_1 \cos \left( \sqrt{\frac{\varepsilon l + Mg}{2M(l - h)}} (1 - \sqrt{1 - i}), t + \eta_1 \right)$$

$$+ \frac{Mg}{2\varepsilon} \left( -\frac{\varepsilon l}{Mg} (1 + \sqrt{1 - i}) + 1 - \sqrt{1 - i} \right) \Lambda_2 \cos \left( \sqrt{\frac{\varepsilon l + Mg}{2M(l - h)}} (1 + \sqrt{1 - i}), t + \eta_2 \right)$$

It thus appears that the amplitude of the principal constituent of s is nearly

$$h_{sl}^{Mg} \Lambda_1$$

while that of the other constituent is nearly  $-l\Lambda_2$ .

To find the best way of starting the pendulum so as to make the ratio of  $\Lambda_2$  to  $\Lambda_1$  as small as possible, we must consider how to make the initial value of s as nearly as possible  $h \frac{Mg}{\epsilon l}$  times the initial value of  $\varphi$ . Now, it is easy to see that if the pendulum is supported at a point at a distance x from the knife-edge, any yielding of the support will diminish the value of  $\varphi$  as expressed by the equation

$$ds = -x \sec \varphi, d\varphi$$
.

Substituting this in the expression for the differential of the potential energy, this last becomes

Mgh sin 
$$\varphi$$
,  $d\varphi - \varepsilon s x$  see  $\varphi$ ,  $d\varphi$ .

Equating this to zero, we find

$$s = h \frac{Mg}{\epsilon x} \sin \varphi \cdot \cos \varphi$$
.

In order that this should be equal to  $h\frac{Mg}{\epsilon l}\varphi$ , it is only necessary to put x=l, so that in starting the pendulum the finger or trigger should be applied at the lower knife edge or center of gyration.]

The elasticity,  $\varepsilon$ , may be measured by observing the deflection, S, of the support produced by a horizontal force equal to the unit of weight. For

$$\epsilon = \frac{g}{S}$$

^{*} It is easy to see that the effect of this would be to increase the last term of the living force; this would affect the second of the differential equations just as if M had been multiplied and h divided by the same quantity. But this would not affect the final result. [1882.]

This is the point to which the greatest objection to my work has been made. [1882.]

Substituting this value, we find

$$\varphi = \frac{A}{h} \cos \left( \sqrt{\left( \frac{g}{l + MS_{l}^{h}} \right)^{t}} \right)^{\frac{1}{2}}$$

Accordingly, the effect on the pendulum is to give it a virtual length greater than what it would have on a rigid support by  $MS_{I}^{h}$ .

Let us denote the duration of an oscillation by T, and let  $\Delta$  be used to indicate the effects of flexure. Then, since

$$T^2 = O^2 \frac{d}{g}$$

we have

$$\Delta T^2 = \frac{O^2}{q} MS_l^h$$

If we distinguish by subjacent letters the two positions of a reversible pendulum, we have

$$g^{2l} = \frac{\mathbf{T}_{d}^{2}h_{d} - \mathbf{T}_{u}^{2}h_{d}}{h_{d} - h_{u}}$$

and

$$\Delta l = MS$$

or putting  $\lambda$  for the length of the second's pendulum

$$\Delta \lambda = MS_{l}^{\lambda}$$

To determine the flexure, I fasten in the slot in the plane of suspension of the Repsold apparatus a fish-line passing horizontally in the direction of the pendulum's movement over an Atwood's machine pulley, and on the end of this cord I hang a kilogramme. [With a stronger support, the pendulum itself may conveniently replace the kilogramme.] On the extremity of the plane of suspension, or at the end of an arm attached thereto,* I stick a glass stage micrometer, turned so as to measure in a direction parallel to the impressed force. This scale is looked at by a microscope carrying a filar micrometer, and solidly mounted upon an independent support, the standard of which is a piece of gas pipe about 10 centimeters in diameter.

I now give a brief résumé of my results, beginning with the experiments to determine the position of the fixed axis about which the head of the Repsold support rotates during flexure.

A.-Experiments made on a level with the suspension plane.

HOBOKEN, March 10, 1877. Temperature 13° C.

			i				

The calculated quantities suppose the axis to pierce the vertical of the forward end of the suspension plane 1^m.07 above this plane. It is notat all surprising that the instantaneous axis is above the suspension plane. Let us suppose that the flexure existed exclusively in three feet of the support. It is case the movement of the upper end of each foot would be perpendicular to the general direction of the foot, and at the same time perpendicular to the radius of the circle of revolution, so that the foot would be directed directly towards the fixed axis. The axis is without doubt behind the support, on account of the flexure of the plane itself.

I made experiments at Geneva, Paris, Berlin, and New York, in order to determine S numerically. The experiment at Geneva, made the 13th of September, was only a trial. But Is had a good pulley which I had borrowed from the workshop of the Geneva society for the construction of physical instruments, and I got as an approximate value—

$$S = 0 \text{ mm.} 034$$

The pulley that I used at Paris had considerable friction, to which can be attributed the fact that the numbers found differ sensibly from those obtained with the aid of better apparatus.

These are the figures-

January 18, 1876, at Messrs. Brünner, Temp. 1° C S=0mm.0363 March 7, 1876, at the Paris Observatory, Temp. 9° C S=0mm.0371

At Berlin I used a very delicate pulley which turned on friction-whels, in order to diminish the friction. It belonged to the Physical Cabinet of the Institute of Technology of Berlin, and was put at my disposition by the kindness of Professor Paalzow. The micrometric readings were made alternately with and without the weight, making but one reading each time, in order to avoid any error arising from the support of the micrometer, this being made of wood. In the readings made alternately with and without the weight, I ended with the arrangement with which I began (11 for one, and 10 for the other), in order that the mean instant of the observations should be the same for the two arrangements. The value of 1 division of the micrometer screw was measured separately.

Below are the results of the different : ries-

May 24, 1876, a. m.,	$S = 0^{mm}.0340$

, , , , , , , , , , , , , , , , , , , ,	0 ^{mm} .0336
Mean,	S=0mm·0339±0mm.001

At Hoboken (near New York) I obtained, through the kindness of Professor Morton, an excellent pull in the workshop of the Stevens Institute of Technology. I always made a recomb length the lines of the scale before changing the disposition of the weight.

^{*}This arm is best made of brass tubing, which may be cut out to make it lighter. [1882.]

The results of the separate series are-

March 7, 1877, Temp. 159 C.,	$S=0^{mm}.0342$
March 10, 1877, Temp. 120.	$0^{\mathrm{min}}.0332$
	$0^{\rm mm}, 0337$
See a se	$0^{\mathrm{min}}.0343$
	$0^{\mathrm{min}}.0342$
	$0^{\mathrm{mm}}$ ,0339
	0 ^{mm} .0334
These two series should have doub	ble\ 0 ^{min} .0342
weight in the reduction,	( 0mm,0342
Wash	S-0mm 0340 ± 0mm 000

In all the experiments made in the different positions of the scale the flexure obtained has been reduced to the center of the knife, and this last is what is called S.

It is to this last value that I give the preference.

It follows, from the experiments described on pages 430-431, made to determine the position of the axis of rotation, that the forward end of the suspension plane is distant from that axis by √1^m.355×1^m.07=1^m.20. And, since the movement of this end with the weight of a kilogramme is-S+0mm,0008, the correction +0.0008 arising from the reduction from the center of knife to the forward end, it follows that the torsion of the support by that force is  $\frac{0^{\text{min}}.0348}{1^{\text{min}}.20} = 0.0000290 = 5.\%8$ .

Although there is nothing to be suspected in this result, I wished to check it by a direct experiment. I attached a mirror at the extremity of the suspension plane, and, with the aid of a telescope, I measured the torsion by the reflection of a scale, and I found it 6". This method, of course, is not as exact as the other.

In order to arrive at another confirmation of the theory, I made the following observations on the flexure produced by the oscillation of the pendulum itself in its two positions, using a tolerably high-power microscope (i. e., magnifying 500 diameters). The scale used was made by Mr. Rodgers, of Harvard College Observatory. It is divided with extreme exactness, the interval between two lines being  $\frac{1}{4000}$  of an English inch. It was fixed 70 millimeters before the center of the knife, which gives a correction to S of +.0019.

If  $\Phi$  is the amplitude of oscillation on each side of the vertical, the double amplitude of the vibration of the scale should be

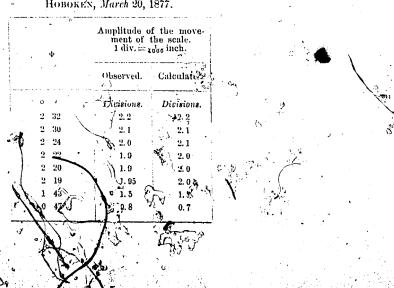

$$2 \text{ M (S} + 0^{\text{mm}}.0019)^{h}_{I} \Phi$$

in which M=6.308 and  $\frac{h}{l} = \frac{17}{56}$  or  $\frac{39}{56}$  according as the pendulum is suspended by the knife nearest or farthest from the center of gravity. I used this formula in calculating the quantities now given.

#### DYNAMICAL FLEXURE.

A .- Pendulum suspended by the knife furthest from the center of gravity.

HOBOKEN, March 20, 1877.

B. ~ Pendulum suspended by the knife nearest the center of gravity

Ί.	`51	0.75	0. 7			

In making these observations, I saw distinctly the little subsidiary vibration at the end of each oscillation arising from the second term of the formula.

Finally, I swung the pendulum on two supports of different flexibility-one was the metallic tripod, by Repsold, to which refer the flexure measurements given above; the other was made by fixing the upper part of the Repsold tripod to a thick wooden plank by means of bronze bolts passing through the three holes through which the feet pass. These holes are conical, and the bolts fit exactly. I put on each bolt between the head of the support and the plank a leaden washer, so that, in tightening the bolts and compressing the washers, great stability was obtained and at the same time a horizontal position. The plank (which was 5 centimeters thick) was cut in order to make a place for the pendulum, and it was placed by force between a stone wall and a brick pillar. A slit was then cut, in which a pulley of an Atwood machine was placed to measure the flexure.

Experiments on the flexure of this support.

HOBOKEN, May 21, 1877.

to th	tance of scale be- re +, behind - of se center of knife English inches.	Distance of scale to suspension plane in English inches + above, - below.	Flexure in millimo- ters under a weight 1 kilogramme.	Temperature C.	Observer,

It follows that for this apparatus = 0mm.0031, and that the difference between the values of S for the two supports is  $0^{\text{mm}}.0309$ . Now I find  $\frac{\pi^2 l}{q} = 1.0125$  sidereal seconds and  $l = 1^{\text{m}}$ . Hence, we conclude that the difference of  $\frac{\pi^2 l}{q}$  according as the pendulum oscillates on one or the other supports must be equal to

$$\frac{\pi^2 l}{g} \frac{\text{M (S-S^1)}}{l} = \frac{81}{80} \times 6.308 \times 0.0309 = 0.000197$$

I swung the pendulum three times on the less solid support and once on the most solid to verify the theory. I observed 10 consecutive passages of the pendulum across the vertical at intervals of 5 minutes, using a relay that I invented for this purpose.

#### A .- Oscillations on the Repsold metallic support.

HOBOKEN, April 1, 1877.

PENDULUM SUSPENDED BY THE KNIFE NEAREST THE CENTER OF GRAVITY.

щоан							,	

Hence, we have

 $T_1^2 = 1^6.0128544$  $T_2^2 = 1^6.0130902$ 

have .

And since  $h_1: h_2 = 101: 44$  we have :

$$\frac{\pi^2 l}{g} = \frac{T_1^2 h_1 - T_2^2 h_2}{h_1 - h_2} = 1.013 \left( 1 - \frac{101 \times 0.0001456 + 44 \times 0.0000902}{57} \right) = 1.012672$$

This value is to be corrected for rate of chronometer and temperature. The chronometer lost  $0^{\circ}.86$  per day, which gives a correction to  $T^{2}$  of  $+0^{\circ}.000020$ . The temperature during the time the heaviest mass was above was  $12^{\circ}.7$  in the mean, and  $12^{\circ}.9$  when this mass was below. Hence, to reduce to  $13^{\circ}$  we must apply a correction of

$$\frac{0.1 \times 101 - 0.3 \times 44}{57} = 0.0000186 = -0.000001$$

Hence we conclude

$$\frac{\pi^2 l}{q}$$
 at 13° C.=1.012691

April 7, 1877.

$$15°.00$$
Temp. heavy end up,  $15°.00$ 

$$\frac{\pi^2 l}{g}$$
 at  $13° = 1.012495$ 

Comparing this value with the one obtained with the other support we find a difference of 0.000198. The difference, according to the computations of the experiments on flexure, ought to have been 0.000197,* which shows a sufficient agreement.

Yours, most faithfully,

[Signed]

C. S. PEIRCE,
Assistant United States Coast Survey.

ON THE INFLUENCE OF INTERNAL FRICTION UPON THE CORRECTION OF THE LENGTH OF THE SECONDS PENDULUM FOR THE FLEXIBILITY OF THE SUPPORT.

It has been shown by Prof. A. M. Mayer that the only sensible resistance to the motion of a tuning fork is proportional to the velocity. In the case of a slowly vibrating body the chief effect is probably due to that lagging of the strain after the stress, which Weber has called the elastic after effect (Nachwirkung). The influence of the former mode of resistance upon the period of oscillation of a pendulum oscillating on an elastic tripod is easily calculated. The same thing cannot, in my opinion, be effected for the other kind of resistance, in the present state of our knowledge; nevertheless, the main characteristics of the motion may be made out. Put

- t, for the time;
- $\varphi$ , for the instantaneous angle of deflection of the pendulum;
- s, for the instantaneous horizontal displacement of the knife edge from its position of equilibrium, in consequence of the flexure of the support;
- l, for the length of the corresponding simple pendulum;
- h, for the distance from the knife edge to the center of mass of the pendulum;
- g, for the acceleration of gravity;
- $\gamma$ , for the ratio of g to the statical displacement of the point of support, which would be produced by a horizontal force equal to the weight of the pendulum;
- a, for the coefficient of internal friction supposed proportional to the velocity.

Then the differential equations are

$$lD^{2}_{\iota}\varphi + D^{2}_{\iota}s = -g\varphi$$
  
$$hD^{2}_{\iota}\varphi + D^{2}_{\iota}s = -\gamma s - aD_{\iota}s$$

The solution of these equations will be of the form (using no for the Neperian base and no for the ratio of circumference to diameter):

$$\varphi = \mathbf{A}_1 \odot^{z_1'} + \mathbf{A}_2 \odot^{z_2'} + \mathbf{A}_3 \odot^{z_3'} + \mathbf{A}_4 \odot^{z_4'}$$

$$s = \mathbf{B}_1 \odot^{z_1'} + \mathbf{B}_2 \odot^{z_2'} + \mathbf{B}_3 \odot^{z_3'} + \mathbf{B}_4 \odot^{z_4'}$$

$$(1)$$

where  $z_1, z_2, z_3, z_4$  are the roots of the equation

$$(l-h)z^{3}+alz^{3}+(\gamma l+g)z^{2}+agz+\gamma g=0,$$

where, for each subscript letter,

and where four arbitrary constants are determined the initial conditions.

The roots of the biquadratic equation are at imaginary, and may be written

$$z_1 = -\tilde{\varepsilon}_1 + \eta_1 \sqrt{-1}$$

$$z_2 = -\tilde{\varepsilon}_1 - \eta_1 \sqrt{-1}$$

$$z_3 = -\tilde{\varepsilon}_2 + \eta_2 \sqrt{-1}$$

$$z_4 = -\tilde{\varepsilon}_2 - \eta_2 \sqrt{-1}$$

Expressing the coefficients in terms of the real and imaginary parts of the roots, the equation becomes

$$z^{4} + 2(\tilde{\xi}_{1} + \tilde{\xi}_{2})z^{3} + (4\tilde{\xi}_{1}\tilde{\xi}_{2}' + \tilde{\xi}_{1}^{2} + \tilde{\xi}_{2}^{2} + \eta_{1}^{2} + \eta_{2}^{2})z^{2} + 2[(\tilde{\xi}_{1}^{2} + \eta_{1}^{2})\tilde{\xi}_{2} + (\tilde{\xi}_{2}^{2} + \eta_{2}^{2})\tilde{\xi}_{1}]z + (\tilde{\xi}_{1}^{2} + \eta_{1}^{2})(\tilde{\xi}_{2}^{2} + \eta_{2}^{2}) = 0.$$

If the terms in  $z^3$  and z were neglected, that is, if  $\alpha$  were neglected, the solution of the false equation so obtained would be as follows (where observe the varying sign of  $\eta_1$ ):

False 
$$z^2 = \frac{1}{2} (4\xi_1 \xi_2 + \xi_1^2 + \xi_2^2 + \eta_1^2 + \eta_2^2)$$

$$\pm \frac{1}{2} (4\xi_1 \xi_2 + \xi_1^2 + \xi_2^2 - \eta_1^2 + \eta_2^2) \sqrt{1 + 4^{4\xi_1 \xi_2 \eta_1^2 - \xi_1^2 (\eta_2^2 - \eta_1^2) - \xi_1^2 \xi_2^2 + (4\xi_1 \xi_2 + \xi_1^2 + \xi_2^2 - \eta_1^2 + \eta_2^2)^2}$$

In the original publication, owing to an erroneous value for the mass of the pendulum, this is erroneously calculated as 0.000191. The agreement of the experiments with theory is, therefore, much better than was supposed.

Now, in the actual case,  $\eta_2$  will be at least 100 times  $\eta_1$ ,  $\mathcal{E}_2$  will be quite large, and  $\mathcal{E}_1$  very small. We may, therefore, neglect the square of the fraction under the radical; and we have very closely

$$\begin{aligned} \text{False } z_1^2 &= \text{false } z_2^2 = -\eta_1^2 + \frac{4\mathcal{E}_1\mathcal{E}_2\eta_1^2 - \mathcal{E}_1^2(\eta_2^2 - \eta_1^2) - \mathcal{E}_1^2\mathcal{E}_2^2}{4\mathcal{E}_1\mathcal{E}_2 + \mathcal{E}_1^2 + \mathcal{E}_2^2 - \eta_1^2 + \eta_2^2} \\ \text{False } z_3^2 &= \text{false } z_4^2 = -\eta_2^2 - \mathcal{E}_1^2 - \mathcal{E}_2^2 - 4\mathcal{E}_1\mathcal{E}_2 \frac{4\mathcal{E}_1\mathcal{E}_2\eta_1^2 - \mathcal{E}_1^2(\eta_2^2 - \eta_1^2) - \mathcal{E}_1^2\mathcal{E}_2^2}{4\mathcal{E}_1\mathcal{E}_2 + \mathcal{E}_1^2 + \mathcal{E}_2^2 - \eta_1^2 + \eta_2^2} \\ \text{False } z_1 &= -\text{false } z^2 = \eta_1 \left( 1 - \frac{1}{2\eta_1^2} \frac{4\mathcal{E}_1\mathcal{E}_2\eta_1^2 - \mathcal{E}_1^2(\eta_2^2 - \eta_1^2) - \mathcal{E}_1^2\mathcal{E}_2^2}{4\mathcal{E}_1\mathcal{E}_2 + \mathcal{E}_1^2 + \mathcal{E}_2^2 - \eta_1^2 + \eta_2^2} \right) \sqrt{-1}. \end{aligned}$$

We thus see that, by neglecting the resistance, we get for the value of  $z_1$  a quantity which requires only a minute correction in order to give the imaginary part of the true  $z_1$ . The same thing is not true for  $z_3$  and  $z_4$ . Now,  $\eta_4$  is  $\odot$  divided by the principal period of oscillation of the pendulum upon the flexible stand. This is the quantity which we wish to determine; the others have only to be known approximately for the purpose of calculating the small correction to this. The logarithmic decrement of the amplitude of oscillation of the pendulum in the unit of time, so far as it is due to internal friction, is the quantity  $\mathcal{E}_1$ . After these two quantities have been approximately ascertained, we may approximate to the quantity  $(\xi_2^2 + \eta_2^2)$  by means of the equation

$$(\mathcal{E}_1^2 + \eta_1^2) (\mathcal{E}_2^2 + \eta_2^2) = \frac{\gamma g}{l - h}.$$

Then, by eliminating a between the two equations  $2(\mathcal{E}_1 + \mathcal{E}_2) = \frac{\gamma g}{l - h}.$   $2(\mathcal{E}_1 + \mathcal{E}_2) = \frac{al}{l - h}.$ 

$$2(\xi_1+\xi_2)=\frac{al}{l-h},$$

$$2[(\xi_1^2 + \eta_1^2)\xi_2 + (\xi_2^2 + \eta_2^2)\xi_1] = \frac{ag}{l-h},$$

we obtain  $\xi_2$ , and consequently  $\eta_2$ . The values so obtained must satisfy the equation

$$4\mathcal{E}_{1}\mathcal{E}_{2} + \mathcal{E}_{1}^{2} + \mathcal{E}_{2}^{2} + \eta_{1}^{2} + \eta_{2}^{2} = \frac{\gamma l + g}{l - h}$$

Before proceeding to the consideration of the elastic after effect, I propose to apply the equations thus obtained to the calculation of the correction of the seconds' pendulum for the flexure of the stand, supposing the internal friction to be proportional to the velocity.

For the pendulum used by me we have the approximate values-

l=1.00; h (heavy end up)=0.30; h (heavy end down)=0.70; g (New York)=0.993 ×  $\odot^2$ =9.89;  $\gamma = \frac{1}{0.0002125} = 4706$ ;  $\eta_1 = 1.00$ .

The accompanying table shows that  $\xi_1=0.000008$ . From this we calculate that with heavy end up  $\xi_2=0.08$ ,  $\eta_2=257$ ; with heavy end down  $\xi_2=0.17$ ,  $\eta_2=392$ . From this it appears that the correction of  $\eta_1$  is absolutely insensible, or, in other words, the effect of resistance (supposed propertional to the velocity) vanishes. That this is nearly, in fact, the case for my instrument is shown by the circumstance that the times of oscillation upon stands of different rigidities agree with the values calculated in leaving the internal friction out of account.

The last interval is probably affected by an error in the graduation of the scale used on one of the standa

M. Plantamour proposes to determine the effect of the internal friction of the pendulum stand upon the correction for flexure, by means of the difference between the statical and dynamical flexure. He has made numerous observations, which, according to his own interpretation of them, would show that, if a pendulum be supported in a certain inclined position until the stand has had time to take its position of equilibrium under this force, and then be let go, the ratio of the amplitude of oscillation of the stand to that of the pendulum is not the initial one, but is very different from that. If this were the case, the motion of the stand and pendulum could not be represented, even approximately, in the form (1), for by those equations the logarithmic decrement of the oscillation of the stand is the same as that of the pendulum. It is true that the two parts of the oscillation (nearly in the natural periods of the pendulum and of the stand) have different logarithmic decrements; and, as the ratio of their amplitudes is not the same for the stand and for the pendulum, a certain change in the total relative amplitude might occur. in this way, but only an excessively minute one, nothing like what M. Plantamour thinks he has observed. But it is so improbable that the motions of the stand and pendulum depart much from the forms (1) that it would be wrong to accept M. Plantamour's results until they are confirmed by a purely optical observation free from any possible influence from the machinery attached to the stand. Such an observation has been made by me, and, though I admit it was rather rough, it is entirely opposed to M. Plantamour's conclusions. Should the latter be confirmed, they would totally mullify the attempt to correct for the effect of flexure, as they would show the inapplicability of the analysis which has been proposed for the solution of that problem without affording us much hope of being able to replace it; and it would seem to be necessary the case to reject all the work which has been done with the reversible pendulum.

If the pendulum were started in the manner proposed, and if for any cause the amplitudes of pendulum and stand were altered in different ratios, there would be a perpetual force at work tending to restore the old ratio, so long as the phases of the motion were the same in the pendulum and stand. But, if the phases differed, a part of this force would go to diminishing the amplitudes, and would act so strongly in this way that there would be a rapid decrement on account of this circumstance. Suppose, for instance, that in the differential equations we were to put instead of  $D_t^2s$ ,  $D_t^2s_1$ , where s is the value of s at a time later than t by a constant. The result of this would be (neglecting terms involving a) that instead of the square of the exponent of the Naperian base bying the sum of two negative quantities, one of them very small compared with the other, the smaller of these quantities would be multiplied by an imaginary root of unity. This would have but little effect on the imaginary part of the exponent of base, which determines the period; but it would add a considerable real part, which would represent a corresponding decrement of arc.

It seems difficult to conceive of a force which should greatly change the relative amplitudes of oscillation of the pendulum and stand, without at the same time producing an enormous decrement of the amplitude of oscillation, such as certainly does not exist. It is for those who believe that the existence of such a force has been experimentally proved to show how great an effect it would have upon the period of oscillation. M. Plantamour supposes that the formula given by me in my paper, "De l'influence de la flexibilité du trépied sur l'oscillation du pendule à reversion," would still.apply to such a case; but I am unable see upon what ground.

Meantime, in the present state of the question, it appears to me that we must appeal to direct experiment to determine the difference between the time of oscillation on a stiff and on a flexible stand. Such experiments were given by me in the paper above mentioned, and I have since greatly multiplied experiments on a stiff stand, with the general result there announced, namely, that the difference is slightly greater than my theory supposes (owing, perhaps, to neglecting the energy of movement of the support), and not smaller, as M. Plantamour's views would require.

ON THE EFFECT OF THE VERTICAL ELASTICITY OF A PENDULUM SUPPORT.

Let s = the amount of depression of the support below its mean position;

e =the force of restitution;

l = the length of the simple equivalent pendulum;

h = the distance of the point of support from the center of mass of the pendulum;

 $\varphi$  = the angle which the axis of the pendulum makes with the vertical;

r = the perpendicular distance of a given particle of the pendulum from the knife-edge;

 $\omega$  = the angle which r makes with the plane through the knife edge and the axis of the pendulum.

The horizontal velocity of a particle m is

$$r \cos (\dot{\varphi} + \omega) D_i \varphi$$
.

The vertical velocity is

$$r\sin(\varphi+\omega)D_t\varphi-D_ts$$
.

The vis viva of the particle is, then,

$$\frac{1}{2}mr^2(\mathbf{D}_i\varphi)^2 - mr\sin(\varphi + \omega)\mathbf{D}_i\varphi \cdot \mathbf{D}_is + \frac{1}{2}m(\mathbf{D}_is)^2.$$

The vis viva of the pendulum is

$$\frac{1}{9}\mathbf{M}lh(\mathbf{D}_t\varphi)^2 + \mathbf{M}h\sin\varphi\mathbf{D}_t\varphi\cdot\mathbf{D}_ts + \frac{1}{9}\mathbf{M}(\mathbf{D}_ts)^2.$$

The potential energy of the pendulum is

$$\mathbf{M}g(h-h\cos\varphi)+\frac{1}{2}es^2.$$

Lagrange's equations are consequently

$$\begin{aligned} & Mlh D_t^2 \varphi - Mh \sin \varphi D_t^2 s = -Mgh \sin \varphi, \\ & - Mh \sin \varphi D_t^2 \varphi - Mh \cos \varphi (D_t \varphi)^2 + MD_t s = -es. \end{aligned}$$

If S be the amount by which the stand is statically compressed by the weight of the pendulum, then e=Mg:S, so that the equations become

$$lD^{2}_{t}\varphi - \sin\varphi D^{2}_{t}s = -g\sin\varphi,$$

$$-h\sin\varphi D_{t}\varphi - h\cos\varphi (D_{t}\varphi)^{2} + D^{2}_{t}s = -\frac{g}{8}s.$$

$$(2)$$

It is evident that small changes in  $\varphi$  will affect s insensibly, so that in determining s we may assume

$$\sin \varphi = \varphi, \quad \cos \varphi = 1, \quad \varphi = \Phi \cos \sqrt{\frac{g}{it}}$$

The second equation then becomes

$$D^{2}_{i}s + \frac{g}{S}s = -\frac{gh\Phi^{2}}{l}\cos 2\sqrt{\frac{g}{l}}.t, \qquad \bullet$$

whence

$$s = \frac{hS}{4S - l} \Phi^2 \cos 2 \sqrt{\frac{g}{l}} t + C \cos \sqrt{\frac{g}{S}} (t - t_0).$$

The second term may obviously be neglected, and 48 may be neglected in comparison with l, so that

$$s = -\frac{hS}{l} \Phi^{2} \cos 2 \sqrt{\frac{g}{l}} t,$$

$$D^{2}_{l} s = \frac{4ghS}{l^{2}} \Phi^{2} \cos 2 \sqrt{\frac{g}{l}} t = \frac{4ghS}{l^{2}} (2\varphi^{2} - \Phi^{2}).$$

Then the first equation becomes

$$D^{2}, \varphi = -\frac{g}{l} \left( 1 + 4 \frac{Sh}{l^{2}} \Phi^{2} \right) \varphi + \frac{g}{6l} \left( 1 + 48 \frac{Sh}{l^{2}} \right) \varphi^{3},$$

after substituting  $\varphi - \frac{1}{6}\varphi^3$  for  $\sin \varphi$ , &c. Or, more briefly,

$$D_{c}^{2} \varphi = -g' \varphi + \frac{1}{6} g'' \varphi^{3}$$

Putting 
$$\varphi = \sqrt{\frac{g'}{a''}}\theta$$
, we get

$$D_{\ell^2}\theta = -g'\theta + \frac{1}{6}g'\theta^3,$$

whence

$$T = \mathfrak{O}\sqrt{\frac{l}{g'}} \left(1 + \frac{1}{16} \Phi^{2}\right)$$

$$= \mathfrak{O}\sqrt{\frac{l}{g}} \left(1 + \frac{1}{16} \frac{g''}{g'} \Phi^{2}\right)$$

$$= \mathfrak{O}\sqrt{\frac{l}{g}} \left(1 - \frac{2Sh}{l^{2}} \Phi^{2}\right) \left(1 + \frac{1}{16} \Phi^{2} + \frac{3Sh}{l^{2}} \Phi^{2}\right)$$

$$= \mathfrak{O}\sqrt{\frac{l}{g}} \left(1 + \frac{1}{16} \Phi^{2} + \frac{Sh}{l^{2}} \Phi^{2}\right).$$

If  $\frac{S}{l} = .0001$ ,  $\frac{h}{l} = .7$ , and  $\Phi = .05$ , then  $\frac{Sh}{l^2}\Phi^2 = .000000175$ .

so that the effect of the vertical elasticity of the support is misensible in ordinary cases.
